1. Carving Nature at its Joints

1.1. Tao and the Art of Knife Maintenance

Good chefs know the importance of maintaining sharp knives in the kitchen. What’s their secret? A well-worn Taoist allegory offers some advice. The king asks about his butcher’s impressive knifework. “Ordinary butchers,” he replied “hack their way through the animal. Thus their knife always needs sharpening. My father taught me the Taoist way. I merely lay the knife by the natural openings and let it find its own way through. Thus it never needs sharpening” (Kahn 1995, vii; see also Watson 2003, 46). Plato famously employed this image as an analogy for the reality of his Forms (Phaedrus, 265e). Just like an animal, the world comes pre-divided for us. Ideally, our best theories will be those which “carve nature at its joints”.

While Plato employed the “carving” metaphor to convey his views about the reality of his celebrated Forms, its most common contemporary use involves the success of science -- particularly, its success in identifying distinct kinds of things. Scientists often report discovering new kinds of things -- a new species of mammal or novel kind of fundamental particle, for example -- or uncovering more information about already familiar kinds. Moreover, we often notice considerable overlap in different approaches to classification. As Ernst Mayr put it:

No naturalist would question the reality of the species he may find in his garden, whether it is a catbird, chickadee, robin, or starling. And the same is true for trees or flowering plants. Species at a given locality are almost invariably separated from each other by a distinct gap. Nothing convinced me so fully of the reality of species as the observation . . . that the Stone Age natives in the mountains of New Guinea recognize as species exactly the same entities of nature as a western scientist. (Mayr 1987, 146)

Such agreement is certainly suggestive. It suggests that taxonomies are discoveries rather than mere inventions. Couple this with their utility in scientific inference and explanation and we have compelling reason for accepting the objective, independent reality of many different natural kinds of things. They are the scientific meat between the joints along which good theories cut. The goal of this introductory essay is to survey some important contemporary trends and issues regarding natural kinds,
filling in the picture with key historical episodes. We conclude with a synopsis of the essays contained in the volume.

1.2. Applying the Metaphor

Not everyone appreciates Plato’s metaphor. Some dislike its bloody connotations. Perhaps we should refocus on garment deconstruction and speak of “cutting nature at the seams” instead. Some find it difficult to make much sense of the metaphor. Even if actual butchery, past or present, bears out the Taoist ideal of the knife that never needs sharpening, what sense can we give to “nature’s joints”? While there is undoubtedly much agreement about how to classify nature, it is not always clear how to interpret this. As Rosenberg (1987) reminds us, even impressively widespread cross-cultural classificatory prejudice might reflect our shared way of seeing the world -- a human prejudice -- rather than the reality of the divisions themselves.

Moreover, while agreement is common, so is disagreement. For example, the dispute about the proper definition of biological species has worn on long enough to have acquired a name: The Species Problem. It leads many people to suggest that there are multiple acceptable ways of carving up biological reality, none of which is privileged over the others. If so do we thus lose reason for thinking there are natural kinds, at least at this level of granularity? Though the metaphysical status of species has been a key battleground over questions about natural kinds, there are many others discussed below and in the following essays. In general, we might want an answer to what Ian Hacking has called a “gentle metaphysical question”: “are there natural kinds -- real or true kinds found in or made by nature?” (1990, 135).

Broadly speaking, philosophers have pursued two different strategies for fleshing out an answer. First, we may ask after the metaphysics of natural kinds. What (to press Plato’s metaphor further) is the “skeletal structure” of nature? Joints are gaps. What are they gaps between? At first blush, it would seem that natural kinds are defined by similarity (Quine 1969). Things that are perfect duplicates would seem to be paradigm cases of members of a pristine natural kind. But there are several problems with this line of thought. First, the criterion is too loose. Perfect similarity is not sufficient for making the similar objects a natural kind. Imagine a factory stamping out perfect copies of a widget: few would wish to say that these widgets thereby form a natural kind. Second, the criterion is too strict. Requiring perfect similarity among instances of natural kind would leave us without many of the kinds to which we are pre-theoretically committed. ‘Metal’ or ‘Tiger’ each plausibly names a natural kind of thing. Yet we do not expect all metals or tigers to be perfect duplicates of one another. What we need, it seems, is a sense in which things can be similar enough to one another in a scientifically-relevant way.
This leads us to a second strategy for identifying natural kinds: look toward their use. As we shall see, this strategy can come in either pure or mixed varieties. Let’s start with the mixed (we’ll purify in the next section): letting the purposes to which we put natural kinds inform our approach to their metaphysics. Consider Hempel’s observation that:

> [t]he vocabulary of science has two basic functions: first, to permit an adequate description of the things and events that are the objects of scientific investigation; second, to permit the establishment of general laws or theories by means of which particular events may be explained and predicted and thus scientifically understood; for to understand a phenomenon scientifically is to show that it occurs in accordance with general laws or theoretical principles. (Hempel 1965, 139)

In addition to aiding conceptualization and communication, grouping particular things on the basis of shared properties, regularities, dispositions, natural laws, and so forth enables understanding and control. We seek generalizations about what properties things have in common, what they do, how they behave. Establishing “general laws” which apply not only to particular objects, but kinds of objects allows us to explain and predict. On this model, large swaths of “the vocabulary of science” will necessarily become bound up with general laws. Ernest Nagel noted this connection when he wrote that:

> The statement that something is water implicitly asserts that a number of properties (a certain state of aggregation, a certain color, a certain freezing and boiling point, certain affinities for entering into chemical reactions with other kinds of substances, etc.) are uniformly associated with each other. . . . (Nagel 1961, 31, fn32)

Thus, a more nuanced metaphysical picture of natural kinds emerges: kinds as the extensions of nomic predicates -- predicates that would appear in statements of natural laws.

Though appealing for a number of reasons, the nomic-predicate approach has its difficulties. First, though there are several competing accounts of natural laws, philosophers seem far from consensus over which is correct. Second, many of these accounts do not apply to rather large swaths of science -- even where we suspect that there may be natural kinds. But while few recognize the existence of laws concerning particular species (see Lange 1995, 2004; Mitchell 2000; Woodward 2001), many would like to regard them as natural kinds. Then again, many would not. Finding an adequate account of natural kinds is thus complicated by disagreement both over what natural kinds should ideally do for us -- both in and out of science -- and whether categories of things are in fact natural kinds. Before addressing this strategy
and its complications in more detail, we shall mention one further confusion encouraged by the phase ‘natural kind’.

1.3. The “Naturalness” of Natural Kinds

Recall that Hacking’s gentle question asked whether there were kinds “found in or made by nature”. It is not entirely clear how this modifier should be interpreted. Nor is it clear that the modifier is appropriate. Granted, it commands some plausibility. As LaPorte notes, adhering to something like it countenances paradigmatic kinds like tiger, elm, and water. “Toothpaste, lawyer, and trash, on the other hand, fail to qualify as natural kinds” (2003, 16). But further reflection reveals “being found in nature” is implausible as either a necessary or sufficient condition for being a natural kind:

Not all human-made kinds fail to be natural kinds. Humans have produced minerals, such as quartz and diamond, in the lab. Humans have also produced elements. Technetium is a synthetically produced element that has not been found to occur naturally on Earth. And humans have created new species of plants by inducing polyploidy. Not only are not all natural kinds produced in nature, but not all kinds in nature are natural kinds: Consider mud, dust, or shrub. These are too close to toothpaste and trash kinds to count as natural. Natural kinds are not distinguished by being found in nature.

(LaPorte 2004, 18)

To foreclose on a system’s objectivity due to “contamination” by human activity in general would be rash, even if certain kinds of human activity tip us off about such obviously non-objective cases. It seems to be something about the character of those classification systems more than our simple complicity in their formation. Whatever one thinks of the underlying ontology, systems of classification are undeniably human artifacts -- we are certainly involved in their creation.

More likely, the ‘natural’ compliment refers to some collage of a kind’s being a non-arbitrary, non-subjective, relatively elite grouping of things that is important to science. However, as we shall explain in more detail in §4.3, there may be reason to want to free natural kinds from the exclusive dominion of science. Perhaps there are social kinds or ethical kinds or metaphysical kinds that also, somehow, deserve to be called ‘natural’. For now, though, let us continue to focus on natural kinds in science and turn to their role in inductive inference.

1.4. Natural Kinds and Inductive Inference

Quine reintroduced the concept of a natural kind into philosophical discussion as part of an agreeably unified treatment of two paradoxes of confirmation: Hempel’s
(1945) ravens paradox and Goodman’s (1983) “New Riddle of Induction”. The ravens paradox can be generated by two plausible claims about confirmation: first, that positive instance of a generalization lends some support to that generalization; and second, that something which confirms a statement also confirms anything that is logically equivalent to it. The first claim is sometimes called “the instantial model” of confirmation. For example, if I’m trying to confirm the hypothesis that all ravens are black, it helps to find an *instance* of that generalization: a black raven. So far so good. Now the statement that all ravens are black is equivalent to the statement that all non-black things are non-ravens. The instantial model says that an instance of a non-black non-raven -- a red fire truck, a blue suede shoe, and so on -- confirms it. But since this generalization is equivalent to our all ravens are black hypothesis, these miscellaneous things apparently confirm it too, opening the door for “indoor ornithology”. That seems wrong.³

Goodman’s “New Riddle” also infects that plausible instantial model of confirmation. Suppose we define a predicate ‘grue’ as applying to anything that is either green and observed before now or blue and unobserved. Assuming all observed emeralds have been green, they’ve all also been “grue” and thus on the instantial model support the conclusion that all emeralds are grue. Assuming that some emeralds are as yet unobserved, this entails the conclusion that some emeralds are blue.

Quine’s solution in both cases was to call upon natural kinds as the extensions of “projectible predicates” to restrict the instantial model. Certain predicates -- ‘raven’ and ‘emerald’ among them -- are posited to be distinguished in science by being confirmable by their instances. While ‘raven’ might name a natural kind, its complement -- ‘non-raven’ -- does not. Likewise, ‘green’ might name a natural kind of color, whereas ‘grue’ does not. Rather than seeking some metaphysical foundation for projectibility and letting *that* define natural kinds (what we are calling the “mixed approach” above), the present strategy puts all of the emphasis on projectibility and has that direct our approach to the metaphysics of natural kinds.

Quine’s move seems productive. There does seem to be something suspiciously “unnatural” and miscellaneous about the grue things and the non-ravens that might interfere with their operating straightforwardly with our confirmatory practices. But as we saw above, it is difficult to say precisely what the compliment ‘natural’ amounts to. Without an answer to this question, we merely replace one difficult problem with another: identifying which predicates are *projectible*. Hacking puts this point nicely: “Projectibility’ becomes the name of an as yet unanalyzed feature of predicates, namely that they are and can be used inductively. Then the new riddle of induction achieves a succinct formulation, ‘Which predicates are projectible?’” (Hacking 1995, 202). But this just prompts the question again: what is it to be a natural kind? On
the other hand, construing natural kinds simply as the extensions of projectible predicates leaves the problem of induction untouched. It looks as though we must choose which bird to pelt with our stone.

Quine toys with the former route, construing natural kinds in a manner Goodman painstakingly avoided: in terms of overall similarity. Ravens are relevantly similar to each other. Non-ravens are not. Though in general cautious about kinds and the allied notion of comparative similarity, he believed the latter notion to be ready to hand in chemistry:

Comparative similarity of the sort that matters for chemistry can be stated outright in chemical terms, that is, in terms of chemical composition. Molecules will be said to match if they contain atoms of the same elements in the same topological combinations. . . . At any rate a lusty chemical similarity concept is assured. (Quine 1969, 135)

Quine saw the objectivity of chemical kinds as secured by their common chemical structure. This is, presumably what makes emeralds, but not non-emeralds, projectible. The italicized qualifier -- “of the sort that matters for chemistry” -- is important here. Presumably, what matters for chemistry is what matters for chemists: the particular reactivity of various chemical stuffs. And clearly, the topological structure of chemical substances’ basic components is here of considerable importance. As we shall see below, Quine’s thought found fertile ground with Kripke (1980) and Putnam (1975), who revitalized a form of essentialism about natural kinds that can be traced back to Aristotle. Free from Quine’s anti-essentialist scruples, they developed a modern version of the Lockean distinction between real and nominal essences. Natural kinds, they claim, are indeed individuated by hidden real essences. Unlike Locke, however, they were quite sanguine about our ability to discover such essences. For them, this was the bedrock upon which objective taxonomies could be built. In the next section, we trace some of this story.

2. The Question of Essentialism

Let us speak for a moment just about the qualitative features of objects -- what philosophers typically call their properties. Properties can be possessed in different ways. Ordinarily, that some object has a property $P$ is an “accidental” matter -- not in the sense of being regrettable or a fluke, but in that it might not not have had that property. For example, while Roger Federer is in fact a tennis player, he might not have been. He could have pursued a different career (and still have been the same person). Federer is also rational. But it is far less clear that he could have lacked this quality (while remaining the same person). If this is right, we say that the quality of rationality is essential to Federer, whereas that of being a tennis player is merely accidental. In general, the essential properties $E$ of an object are those that determine
what that object is. In other words, \( E \) includes those properties upon which the understanding of the object rests. It also includes some of the properties on which its existence depends (there may be others, which are non-essential, and on which its existence also depends.) In the Western tradition, the concept of an essential property dates back to Aristotle; it enjoyed much fortune in Medieval and Modern times, and is still somewhat in vogue nowadays.\(^5\)

2.1. Aristotle on Essences

Even his tennis prowess aside, Federer is a unique individual -- there is literally no one else who is he.\(^6\) On the other hand, he is many things that other people are as well. For example, he is a professional tennis player: one of the many who compete in tournaments. He is also a person: one of the many who inhabit the globe. So we have one individual -- Federer -- who is at the same time many things: he is one but he is also many. And thus we have “the problem of the one and the many.” To solve the problem is tantamount to giving an explanation of kind membership (or at least of possessing a property).

Plato tried to make sense of kind membership by positing a relation of “taking part” or “participation” in a kind or a property (what Plato called “Forms”). For example, Mary and Hannah are both human as they participate in the form of humanity -- an abstract, ideal, non-concrete entity. This is how Plato proposed to understand the “jointedness” of nature: natures joints are defined by the Forms. Yet Plato himself presented formidable objections to his own project in the Parmenides -- some of which seemed to others as more compelling than the view itself. For this reason, perhaps, Aristotle set out to provide a different metaphysics. But as Karl Popper once put it, while Aristotle denied “Plato’s peculiar belief that the essence of sensible things can be found in other and more real things...[he] agreed with him in determining the task of pure knowledge as the discovery of the hidden nature or Form or essence of things” (Popper 1950, 34). A pillar of the novel metaphysics was Essentialism, upon which Aristotle elaborates most famously in the Categories, the Metaphysics, and the Posterior Analytics.

In Categories 2 and 3, Aristotle draws some distinctions which provide the logical foundation for postulating the existence of essences. First of all, he claims that there are two kinds of predications: to say of and to be in. If B can be said of A, then B’s definition can be predicated of A. On the other hand, if B cannot be said of A but it is in A, then B’s definition cannot be predicated of A. For example, we can say of Rubi that he is a dog because whatever defines being a dog also defines Rubi. On the other hand, whiteness is in Rubi but cannot be said of Rubi, as he is not defined by whiteness, though of course, something else -- e.g., snow-- may be defined by whiteness. Although it appears that the focus of the Categories is to furnish guidelines
for classificatory purposes, the distinction between “saying of” and “being in” is already a hint of the essentialist attitude more explicitly advocated in other works.

From here, Aristotle distinguishes four kinds of entities: “Of things themselves some are predicable of [said of] a subject, and are never present in a subject … Some things, again, are present in a subject, but are never predicable of [said of] a subject … Other things, again, are both predicable of [said of] a subject and present in a subject … There is, lastly, a class of things which are neither present in a subject nor predicable of [said of] a subject, such as the individual man or the individual horse. But, to speak more generally, that which is individual and has the character of a unit is never predicable of a subject” (Aristotle, Categories, 2). Following the standard scholastic interpretation of the “ontological square”, we can devise: (i) primary substances, such as Rubi, that can neither be said of nor be in other entities; (ii) secondary substances, such as dogness, that can be said of some other entity but that cannot be in other entities; (iii) universal accidents, such as whiteness, that can both be said and be in other entities; (iv) individual accidents, such as Rubi’s whiteness, that can be in other entities but cannot be said of other entities.

From this analysis of predication Aristotle draws the conclusion that individuals (what he refers to as “primary substances”) are the ultimate constituents of reality because they cannot be predicated, in any way, of other entities. You can say:

1. Socrates is wise

but you cannot meaningfully say:

2. Wisdom is Socrates

because Socrates is a kind of entity that cannot be predicated, in any way, of other entities. Essences belong to (ii), while accidents may belong to (iii) or (iv). The distinctions drawn here, however, were meant mostly for classificatory purposes. How did Aristotle justify the postulation of essences in metaphysical terms?

To answer this question we should look into the Metaphysics, one of Aristotle’s more mature works, especially books VII and XII, where the distinction between form and matter emerges more starkly. Here too he portrays the essence of an individual as that which defines it and without which it could not exist: “For the essence is precisely what something is … Therefore, there is an essence only of those things whose formula is a definition” (Metaphysics, VII, part 4). But a new piece is added to the view: essences are now related to forms: “and so Plato was not far wrong when he said that there are as many Forms as there are kinds of natural objects” (Metaphysics, XII, part 3). Yet, Aristotle holds that Plato was wrong in claiming that forms by themselves are enough: “and so to reduce all things thus to Forms and to eliminate the matter is useless labour; for some things surely are a particular form in a particular matter, or particular things in a particular state” (Metaphysics, VII, part
Thus, Aristotle sketches a theory of essences and individuals that will survive until present times.

In the *Posterior Analytics* Aristotle refines his theory of essences in the context of providing a secure path to knowledge. He puts forward a model of scientific explanation known as the Connecting Term Model according to which the fact $A$ explains the fact $C$ in virtue of another fact -- $B$ -- which connects $A$ to $B$ and $B$ to $C$. Why does eating sugar ($A$) necessarily make you gain weight ($C$)? Because eating sugars ($A$) necessarily increases your bodily fat ($B$) and increasing your bodily fat ($B$) necessarily makes you gain weight ($C$). Aristotle’s view stresses the necessity of the tie between the *explanandum* and the *explanans*, thus bringing what he regarded as decisive evidence in favor of essentialism: “Demonstrative knowledge must rest on necessary basic truths…Now, attributes attaching essentially to their subjects attach necessarily to them… It follows from this that premisses of the demonstrative syllogism must be connexions essential in the sense explained: for all attributes must inhere essentially or else be accidental, and accidental attributes are not necessary to their subjects” (*Posterior Analytics*, I.6).

Aristotle’s model for scientific explanation had a great impact on the future understanding of scientific method and constituted a knockdown argument against those who took a skeptical attitude towards essentialism: in a way, it proved that, if scientific findings increase to any extent our knowledge, then they must do so by means of necessary connections; and said connections require essential attributes if they can be deemed necessary at all.

### 2.2. Locke on Essences

The tremendous success of Aristotle’s metaphysics across the centuries secured the prominence of essences, granting them a chief role in the explanation of kind membership. Along this trail, philosophers’ understanding of essences (and philosophical appreciation of their virtues and vices) changed dramatically. We won’t have the space here to survey these changes, except to consider a modern doctrine of essence whose import is still felt: that of John Locke.

During the early modern period epistemological issues had undermined much of the Scholastic philosophical tradition -- and the Aristotelian doctrine of essences was no exception. Despite its previous success, it was on the brink. Even while granting that essential properties play a key metaphysical and conceptual role in delineating nature’s joints, the means through which we come to gather information about these essences seem obscure. After all, it’s by his accidental properties (his elegant appearance, calm demeanor, and incredible tennis prowess) that Federer is known as an individual. Likewise, it seems that different natural kinds are regularly, though imperfectly, associated with their merely accidental properties. Gold, for example, is
ordinarily identified by certain superficial properties: it’s the stuff that’s a shiny yellow ductile metal for which people often pay dearly. Are any of these properties essential to gold? Just how, in general, should we tell the difference between accidental, superficial properties and those which are essential to their bearers? How do we distinguish between what merely happens to be so and what must be?

The Empiricist philosopher John Locke took these questions quite seriously and advanced a novel proposal. First of all, he defined a quality of a subject as “the power to produce any idea in our mind” (Essay Concerning Human Understanding, II.8.8). Next, he distinguished between primary and secondary qualities: the former being “utterly inseparable from the body, in what state soever it be” (Essay Concerning Human Understanding, II.8.9), the latter being the powers of the objects “to produce various sensations in us by their primary qualities” (II.8.10). Intuitively, the superficial properties of gold are its secondary qualities -- the way it looks to us when we first encounter it in everyday experience. The primary qualities, on the other hand, are those which remain hidden to our senses but which specialized reasoning might reveal. Locke listed “solidity, extension, figure, and mobility” (II.8.10); we might list a certain atomic structure, a typical charge or specific weight, and so on. Locke also considered a third category of qualities, bare powers -- powers of objects to modify other non-mental objects, such as the power of a key to open a lock. But we shall focus on the first two categories.

Locke’s division among qualities of objects moved from epistemic considerations. By definition, a quality is that which produces an idea in the mind. A champion of empiricism, he believed that if you cannot reliably come to know something through experience, you cannot even say that it exists. This allowed him a fresh start also with respect to scientific essentialism, the stronghold of Aristotelian essentialism. Locke distinguished between a substance’s nominal essence -- “The measure and boundary of each sort or species, whereby it is constituted that particular sort, and distinguished from others, is that we call its essence, which is nothing but that abstract idea to which the name is annexed” (III.6.2) -- and its real essence -- “that real constitution of anything, which is the foundation of all those properties that are combined in, and are constantly found to co-exist with the nominal essence” (III.6.6). He then argued that our ideas of substances associate only with their nominal essences: “take but away the abstract ideas by which we sort individuals, and rank them under common names, and then the thought of anything essential to any of them instantly vanishes” (III.6.4). Precisely for this reason, he himself seemed ambivalent about our ability to fully grasp real essences. After all, our ideas of substances associate only with their nominal essences since we lack “microscopical eyes” to see real essences. Thus with Locke a new form of essentialism came into the picture, which sees essences as abstract ideas that are applied to individuals -- that is,
a view which sees essences as sorts. As we shall see, we can identify a parallel
distinction between a sortal understanding of essences and an Aristotelian one in
contemporary philosophers’ treatments of these matters.

Almost a century after Locke published his *Essay*, David Hume’s empiricism
determined essentialism’s fate for the next two centuries within the philosophical
community of England (and much of continental Europe too). The cultural
environment in which twentieth century philosophers of science were writing,
steeped in such empiricism, had little truck with such seemingly occult notions. The
only sort of necessity worth having was a purely linguistic matter. It is through this
lens that we may appreciate how dramatic was the revival of essentialism within the
second half of the twentieth century. Two quite distinct branches can be recognized
in this process: on the one hand we have the sortal tradition (§3.3), on the other the
Kripkean-Putnamian one (§3.4).

2.3. A Metaphysical Rebirth of Essentialism

The intuition that nature can be carved up into different *sorts* of things and that each	hing is something of some sort lies at the basis of a widespread metaphysically-
motivated revival of essences. Still revered by many, this sortal tradition, which
flourished primarily in England, engrained a Lockean approach to essential
properties and the close analysis of natural language. But the underlying doctrine is
less homogeneous than it might first appear. Indeed, even if many defended a theory
of sortals, few agreed on the meaning of this term. Following Feldman (1973), we can
distinguish three necessary requirements that a predicate $P$ has to satisfy to be a
*sortal*: *

i. A predicate $P$ is a sortal only if $P$ singles out an individual;

ii. A predicate $P$ is a sortal only if $P$ is the partial or whole essence of
the individual it singles out;

iii. A predicate $P$ is a sortal only if, when $P$ applies to an individual $x$, $P$
cannot belong to any proper part $y$ of $x$.

Arguably, (i), (ii), and (iii) serve different metaphysical purposes. Yet, there is no
agreement between sortal theorists as to which of them a *sortal* should satisfy. At any
rate, we may leave this issue on a side, as the sortal tradition had a considerably
smaller impact over the debate on natural kinds than that initiated by Saul Kripke
and Hilary Putnam. To this tradition we now turn.

2.4. A Scientific Rebirth of Essentialism

In the 1970s, Kripke (1972, 1980) and Putnam (1975) independently defended the
existence of essences -- via rather different considerations. At that time, Kripke was
trying to offer a theory of reference which would account for -- among other things --
the way in which natural kind terms function. The theory revamped the idea that the identity of an individual is necessary, that it is fixed in every possible scenario. Essences offered a handy explanation of this: the identity of an individual is fixed because it has some essential properties. As we have seen, however, at this point we face the epistemic challenges that confronted Locke.

Here lies Kripke’s main innovation. He conjectured that essential properties are directly linked to our linguistic practices (such as naming) and our scientific concepts (such as genetic identity). Whereas previous theories of reference had it that names referred to individuals by way of descriptions, Kripke argued instead that a name reaches its bearer directly and continues to refer even if the properties we in fact use to identify it are missing. The name ‘Federer’ does not merely refer to that calm, elegant, person of Swiss origins who has won a certain number of tennis tournaments, but to that guy. The idea is that there is something essential about Federer since the first time we called him that name -- perhaps something about his genetic makeup or origins (having the parents she did). Kripke moved to extend this plausible idea about proper names to natural kind terms. When we first referred to ‘water’, say, we refer not to whatever satisfies certain characteristic properties (being clear, potable, liquid at standard temperature and pressure, and so on), but to that stuff. And when scientists discovered that that stuff was H2O, they discovered the essence of water. Kripke produced an elegant proof that all identities were necessary identities.

Putnam’s considerations on essences also proceeded from semantic considerations. Specifically, they grew out of the attempt to furnish a broader theory of meaning. In a deeply influential paper, “The Meaning of ‘Meaning’” (1975), he distinguishes between two types of content: narrow and wide. Narrow content reflects the psychological state of an individual in isolation, whereas wide content includes content which is not part of that individual’s thoughts but is nevertheless entailed by them. The existence of wide content suggests the existence of essential features of reality. For if the meaning of what we say about certain natural kinds (water, for example) is fixed in part by the essence of that kind, then we have good reason for accepting the existence of essences. Suppose we talk about this glass of water: its identity is not just fixed by the perceptual experience that you are having or what qualities you generally associate with water, but also by the very essence that the stuff we call “water”. What is that essence? Well, one very plausible answer is that it is the properties which explain the co-occurrence of those superficial, “nominal” properties, whose essence is presumably (partially) captured by the molecular formula H2O.

After Kripke and Putnam’s contributions, the discussion of essential properties within the philosophy of science got a fresh start. They were able to bring back this
notion in a way that was *prima facie* immune from the suspicion surrounding much of the Ancient, Scholastic, and Modern usages of it. Whether this is so is still a matter of much debate.

Let us consider one final twist in the story of essentialism about natural kinds. Plausibly, the role they play in scientific endeavors turns on their association with law-like behaviors. We see the names of natural kinds habitually turn up in statements about natural laws. One might deny that this is coincidental and simply claim that kinds are law-involving, or *nomic*, predicates. But then the question becomes: *what is it to be a nomic predicate? What are laws in general and what explains their apparent generality and necessity?*

*Scientific Essentialism* attempts to answer this second question. The term first appeared in “The Philosophical Limits of Scientific Essentialism” (1987), by George Bealer. In that article, Bealer criticized Kripkean-style essentialists, according to which essential properties can be discovered *a posteriori*. Despite Bealer’s aims, a number of influential authors embraced scientific essentialism and refined its metaphysical underpinnings (Bigelow, Ellis and Lierse 1992; Ellis and Lierse 1994; Ellis 2001; Bird 2007). In its present form, scientific essentialism is a hardcore metaphysical view, according to which kinds exhibit law-like behaviors as manifestations of the *dispositions* which define them. Dispositions, roughly speaking, are abilities to act in one way or another, given certain circumstances. On this view, laws of nature are *immanent* to the entities possessing certain dispositions. Although Kripke and Putnam never ventured into these sorts of metaphysical speculations, the gist of scientific essentialism owes a great deal to their revival of essentialism and to Kripke’s suggestion that the essences of natural kinds may be discovered *a posteriori*.

By construing laws as manifestations of the essential dispositional natures of different natural kinds of things, Scientific Essentialists effectively solve two problems about laws of nature and their relation to natural kinds. First, the vague intuition that natural kinds were somehow implicated in natural laws becomes precise and understandable. Second, by making the laws expressions of the *essential* nature of different kinds, Scientific Essentialists dispense with one of the most difficult problems in giving an account of natural laws: making sense of their apparently “intermediate” strength of necessity. Essentialists thus hold that not only are the laws somehow more robust than accidental generalizations, but that they *had* to be just the way they are.
3. Applications

3.1. Physico-Chemical Kinds

Chemical kinds have long been a favorite example of essentialists. For as both Quine and Putnam noted, it seems quite plausible that the sort of similarity that would matter for this domain would be molecular structure: the arrangement of certain kinds of atoms. Putnam claims that the essence of water -- what it is to be water -- is to have the molecular structure denoted by ‘H₂O’. The superficial properties we associate with water -- for example, its being a good solvent for certain types of compounds -- are explained by its structure. More specifically, the structure plus the character of its constituent atoms gives rise to these properties.

How then should we understand what divides atoms into different kinds? An analogous story seems likely: the arrangements of sub-atomic particles (viz., protons, neutrons, and electrons) explains why oxygen covets electrons so and why hydrogen is comparatively willing to give them up. But then we need a story about the character of these sub-atomic constituents. What explains why protons have the charge and mass that they do? According to the Standard Model of particle physics, the answer lies in its composition of quarks and their dispositions. Thus, we have a recursive picture of the identity of physico-chemical kinds. The identity of a kind at a certain level of compositional complexity is fixed by arrangements of things at a lower level of complexity. One might wonder at this point whether it is, so to say, “turtles all the way down” or whether complexity bottoms out. Contemporary physics seems to support the latter view. It treats certain kinds (such as quarks and electrons) as fundamental in that they apparently lack structure. They are part of the bottom level of physical complexity and thus kinds whose essence can no longer be understood structurally. On the other hand, the very use of the word ‘atom’ (meaning “something that is partless”) for one of these intermediate levels suggests that we ought be cautious about identifying a particular level as fundamental!

While the foregoing sketch may look quite plausible and unproblematic, there are deep and persistent issues afoot. We have not discussed how reference to physical or chemical kinds is achieved. Is it, as Kripke and Putnam suggest, a direct matter? Reference aside, we might also wonder whether the proffered essences are plausible. Take any glass of water. It is filled with many things that are not composed of H₂O. In addition to various isotopic forms of water (various “heavy waters”, for instance), there are doubtless many other impurities (e.g., minerals, trace elements, dissolved gasses, even micro-organisms). Ditto for the sample initially “baptized” as water. What makes it the case that this initial dubbing fixed on the H₂O sameness relation?
3.2. Biological Kinds

Worries like the foregoing notwithstanding, the essentialist view of natural kinds has seemed compelling enough to extend to higher levels of organization. Hopes initially turned toward extending kindred notions of structure to the biological realm: perhaps tigers have a certain genetic structure which alone makes them tigers. We cannot “define” tigers as, say, fierce striped feline quadrupeds (with whiskers and a tail) because some tigers lack these qualifications (Kripke 1980, 119-120). Just as water might behave differently in different conditions, tigers might get maimed or adopt different behavioral patterns in different environments. Tigers are not easily genetically maimed, though. And their genetic structure is causally upstream from their stripes and fierceness. Insofar as genetic structure remains stable -- serving as an explanation for our habitual association of a certain nominal essence with tigers -- it seems an admirable candidate for the office of “real essence of tiger”. As Robert Wilson characterizes this view: “species essence is not constituted by [observable] morphological properties themselves, but by the genetic properties -- such as having particular sequences of DNA in the genome -- that are causally responsible for the morphological properties” (Wilson 1999, 190).

But again, while initially tempting, this view faces several worries. First, even if we are impressed by the structural account of physical-chemical kinds, we should bear in mind that “genetic structure” and “molecular structure” do not play the same causal role. An organism’s genetic structure does not determine its superficial properties in nearly as direct a way as molecular structure does the superficial properties of homogeneous chemical kinds (see Lewontin 2000, for nice discussion of this point). Second, the fact of evolution and the considerable diversity of species raises the question of whether there even is a genetic essence that all and only the members of a particular species share (see Devitt 2008; Okasha 2002; Walsh 2006; Wilson 1999). Third, many philosophers of biology (e.g., Dupré 1981; Kitcher 1984; Mishler and Donohue 1982), have concluded that we ought be pluralists about biological classification (at least at the rank of species). How might this affect our conviction that species divisions carve nature at its joints?

There is much to say in response to these worries (and there are many other worries besides) and the philosophical community remains largely divided. Some suggest that we can reconfigure our understanding of natural kinds essentialism in light of the majority view in Systematics to accommodate “historical essences” (Griffiths 1999; LaPorte 2004; Okasha 2002). What makes a tiger the kind of thing that it is not some intrinsic genetic property, but a historical property concerning its origin -- its location on the tree of life, say. Others take the common practice of treating species historically as suggesting a radically different metaphysical approach to species. Rather than treat species as kinds, perhaps we should understand them as
individuals -- spatiotemporally extended objects, “hunks of the genealogical nexus” -- perhaps as a way of resisting pluralism about species or rendering it a purely pragmatic issue (Ghiselin 1974; Hull 1978). Others may be content to simply abandon the attempt to extend the metaphor of natural carving to the biological realm. Hacking’s “Gentle Metaphysical Question” is general. It can receive a positive answer without natural kinds being particularly common in science. One could conceivably be pushed all the way back to construing only the fundamental physical particles as natural kinds.

This smacks of parochialism. As Dupré remarks, biology “is surely the science that addresses much of what is of greatest concern to us biological beings, and if it cannot serve as a paradigm for science, then science is a far less interesting undertaking than is generally supposed” (Dupré 1993, 1). Whether or not one agrees with Dupré’s assessment, it seems plausible that many biological categories do play an inferential and explanatory role commonly associated with natural kinds. This puts pressure on the traditional essentialist view of natural kinds.

A number of philosophers have been pursuing a suggestion of Richard Boyd’s (1991, 1999): that there may be a class of phenomena accurately described as “Homeostatic Property Clusters”. This apparently non-essentialist understanding of natural kinds appears better able to make sense of biological diversity. Roughly speaking, Boyd eschews essential properties which “hold together” and explain the co-occurrence of the various superficial properties associated with a kind, suggesting instead that a cluster of properties might secure its own stability, constituting a sort of homeostatic mechanism. Insofar as such homeostatic property cluster (HPC) kinds accommodate our inductive and explanatory practices, we are within our rights to regard them as real (see Williams’ essay below for further discussion).

3.3. All Kinds of Kinds

Thus far, we have restricted our scope to scientific kinds -- and a rather limited swath there. Might our concepts carve nature at other joints besides? In addition to natural kinds of things -- particles, organisms, and so on -- might there be natural kinds of events, processes, forces, laws, states of affairs, and so on? Systematics is but one example of the diverse classificatory practices of the biological sciences. Biologists (both implicitly and explicitly) draw upon a rich stock of biological categories (e.g., “predator”, “decomposer”, “muscle tissue”, “afferent neuron”, “neurodegenerative disease”, and so on) in deepening our knowledge of the organic world.

And what about kinds outside of the natural sciences -- for example, from the social sciences and beyond? There seems to be no a priori reason to exclude these further flung applications. For even non-scientific kinds often seem to come with particular dispositional behaviors entrenched into different kinds of relations. In the
social sciences, we might wonder whether there are genuinely different kinds of people, societies, economic systems, and so on. There is currently a vigorous debate in the philosophy of science concerning the status of racial divisions: do race terms name natural kinds of people (Andreasen 1998; Kitcher 1999; Zack 2002; Pigliucci and Kaplan 2003; Hacking 2005; Glasgow 2009)?

Psychology offers a particularly rich set of examples. Griffiths (1997) has explored the question about whether emotions and other psychological states might be natural kinds. Boyd (1999, 155) even flirts with the notion that the categories “feudal economy” and “capitalist economy” might name natural kinds, finding no difficulties in principle with construing unabashedly human-creations as nevertheless natural in the relevant sense.

What about other conventional-seeming categories? At some point, we may wish to distinguish between natural and social kinds. Consider being a citizen versus being an illegal alien, a sole proprietorship versus a limited liability company, a not-for-profit versus a for-profit business. These are examples of classifications that can play key roles in a society. Their roles are governed not by natural laws but by laws in the more familiar and mundane sense -- each is associated with different rights, duties, and privileges.

There are examples that might be less clearly “natural” or “social”. Consider, for example, those kinds that you find every day in front of you on the shelves of a supermarket or on your plate -- food kinds. A chicken can be free range, an egg certified organic. Although it may be disputed that vernacular expressions are able to pick out natural kinds (Dupré 1993, 26ff), nonetheless they pick out kinds that are important for practical purposes.

Returning to the philosophical terrain, those key formal relations -- such as identity, parthood, membership (in a set), spatio-temporal location -- can be regarded as kinds within the metaphysical realm (Sider 2009). Might there even be natural kinds of absences? On the other hand, consider the role of kinds in ethics (Boyd 1988): moral realists may wish to say that wrong actions comprise a natural kind (or even a hierarchically nested series of natural kinds).

We humans love to draw lines around different portions of the world, so there should be no shortage of fascinating possibilities to consider when we ask whether we are carving nature at its joints.

4. The Essays

So much for introduction. Hopefully you are eager to read the fine essays you have before you.

As we saw above, one of the central roles philosophers have identified for natural kinds is serving as the metaphysical basis for inductive inference. Only predicates in
whose extensions stands a natural kind are “projectible” -- a theme sounded in
different ways by Quine and Goodman. Godfrey-Smith, in “Induction, Samples, and
Kinds” challenges this orthodoxy by suggesting that there are in fact two distinct
varieties of inductive inference that have been run together. In only one of these
varieties does the “naturalness” of kinds play any significant role: at stake in these
inferences are generally dependence relations linking properties. As such, the number
of samples is, in principle, irrelevant to the strength of the inference. If we can
establish the dependence relation by examining only one positive instance, we can get
the generalization in all of its glory. But there is another strategy of inference in
which the strength of the inference to a generalization depends on the quality of our
sampling: in particular, that it is broad and random. Here apparently pathological
cases, like Goodman’s “grue”, can be explained away in familiar terms as certain
kinds of “observation selection effects”. Godfrey-Smith argues that distinguishing
these two inductive strategies can go a long way toward relieving some long-standing
philosophical (perhaps innate!) confusions about induction.

Marc Lange turns his sights on the growing support for scientific essentialism in
his essay, “It Takes More Than All Kinds To Make A World”. As we pointed out
above, elementary physical particles appear to be admirable candidates for natural
kinds if anything is. Assuming something like the Standard Model is correct, they are
intrinsic duplicates defined by a small collection of properties (such as charge and
spin). But -- Lange points out -- if there is something to the modern physical practice
of recognizing different “tiers” of natural laws -- if, for example, there are symmetry
principles that abstract away from particular laws like Coulomb’s Law -- we need to
make sense of certain “counterlegals”, counterfactuals involving breaks of laws.
Scientific Essentialists contend that the essence of charged particles such as electrons
give rise to Coulomb’s Law. But how can the essentialist make sense of counterlegals
such as ‘Had Coulomb’s Law failed to be true, the fundamental dynamical laws
would still have held’? What essence could possibly account for this subjunctive fact?
This is the sense in which it takes more than all of the actual kinds in order to make a
world complete with laws. The Scientific Essentialist would need far more.

Along the way, Lange elaborates a view on the relation between laws and
subjunctives that he defended in his (2000) and more recently in his (2009) and
discusses the vexed question of what makes some properties “natural”, offering the
very interesting suggestion that it might be that a property could be natural in one
possible world and unnatural in another.

In “Lange and Laws, Kinds, and Counterfactuals”, Alexander Bird questions one
of the key contentions in Lange’s paper: that if there had been kinds of particles
other than the actual kinds, the force laws (and laws connecting fundamental and
derivative properties) would still have held. One reason for not accepting this,
suggests Bird, is that we don’t yet know what the fundamental laws are. Perhaps whatever these turn out to be are not as independent from the existence of certain kinds of particles as we are tempted to suppose. Moreover, in at least some cases, we find interesting connections between the existence of certain kinds and fundamental laws. For example, the non-existence of certain conceivable particles (e.g., Helium-2) seems to be governed by fundamental forces (e.g., the strong force). As Bird explains, a natural way of resisting his skepticism involves forbidding “backtracking” reasoning about counterfactuals. But this plausibly both undermines the inference from the claim about the independence of laws and fundamental kinds to other results claimed by Lange and leads to some odd consequences (e.g., that the first event in history -- the Big Bang, possibly -- would have a kind of physical necessity). More generally, Bird suggests that the idea of a hierarchy of laws formed by Lange’s proposal about laws is not quite as secure or important as Lange thinks. This dispute will no doubt continue.

As we mentioned above, one way of thinking about the dispute between those who see laws as necessary and those who believe them to be contingent involves investigating their connection with kinds or properties. Noa Latham pursues the thread in his paper, “Fundamental Laws and Properties”, arguing against the grain that there is in fact no significant distinction between necessitarian views of laws (espoused by the Scientific Essentialists) and contingentist views (e.g., those like Lange who deny that laws are metaphysically necessary). These views are best understood as notational variants of a single view. His argument turns on claims about the metaphysics of property-individuation. For one, that it makes no sense to think about stripping away all of the nomological features of a property, leaving a sort of contingent shell. But from this extreme contingentist view about property identity, there is much leeway -- and possibly no fact of the matter -- about how much we should pack into our concept of properties. There might still be reasons for locating oneself at one end of the spectrum (e.g., the necessitarians do not face the difficult problem of multiplying senses of necessity; contingentists have a more linguistically natural view), but Latham claims that these reasons fall short of the kind of metaphysical strength that their proponents have in mind.

Shifting gears somewhat, Roy Sorensen’s essay, “Para Natural Kinds”, flirts with rejecting the prevalent view that only substances can be natural kinds. What about absences (gaps in an electron shell, craters in the moon)? What about shadows? On reflection, even these “nothings” evince classificatory possibility. Sorensen calls them para natural kinds: absences defined by natural kinds. It’s not surprising that we might have been tempted to treat certain absences as natural kinds, for like reflections they take on many of hallmark features -- lawfulness, projectibility, and so on -- possessed by the natural kinds which define them. Such features allay general
worries about the “subjectivity” of absences. The absence of a chapter in this volume on what kind of doughnut Plato would prefer is a subjective absence salient only to those who might have expected one. In contrast, Sorensen contends that para natural kinds are mind-independent.

The road to essential properties passes through the individuation of their bearers: if something has an essence, then it is something. In his essay, “Boundaries, Conventions, and Realism”, Achille Varzi questions the existence of boundaries between individuals and events of all sorts, thereby disputing the existence of essences’ bearers. His argument moves from the twofold distinction between artificial and natural boundaries (also labelled fiat and bona fide, respectively). When we uncover a natural boundary (one that is not merely fiat), we thereby have a reason to believe that we are in the presence of a genuine individual (or event). On the other hand, when confronted with artificial boundaries, the suspicion of being in the presence of a genuinely artificial individual (or event) surfaces. In his paper, Varzi surmises that all boundaries are artificial, and he substantiates such a thesis by surveying a host of examples -- from geography to biotechnology. From this follows that every individual (or event) is, to some extent, artificial. But from this it does not follow also that anything goes. He concludes by reassuring us that artificial boundaries are, in the end, all that we need “to solve, in an arbitrary but efficient way, coordination problems” of all sorts, and that such a stance is compatible with rigorous metaphysics, such as those advanced by Putnam or Goodman.

But suppose that one were to resist Varzi’s challenge in the name of some form of “realism” about natural kinds and essences; what does it take -- Devitt wonders in his essay “Natural Kinds and Biological Realisms” -- to be such a realist? Moving from the species problem as a case study, Devitt defines realism as that view according to which certain entities play a role that is causally significant because of the kind of thin thing they are (i.e., things that “cut nature at its joints”). This understanding of realism should be kept distinct from two other notions: one according to which realism is committed to the mind-independent existence of certain entities; and another according to which realism is committed to the existence of universals. Devitt thus shows that we ought to keep separate issues about the realism of certain taxa (i.e., the groups of organisms themselves) from issues about the realism of categories (a second-level issue). This sets the stage for considering the recent debate between Mark Ereshefsky’s (1998) “pluralistic anti-realism” and “pluralistic realists” such as Philip Kitcher (1984) and John Dupré (1993). Devitt argues that the clash between these two views is merely apparent: at stake is not the mind-independent existence of species, but rather whether species categories have a sufficiently robust explanatory significance compared to other scientific kinds. Devitt’s suggestion is that the plausibility of the pluralist position with respect to the species problem is
evidence of their minor explanatory role. He concludes by arguing that higher taxa play an even more modest explanatory role and, thus, that the Linnaean hierarchy should be dispensed with.

We noted the above controversy about biological essentialism. In his essay, “Three Ways of Resisting Essentialism about Natural Kinds”, Bence Nanay argues that contemporary biological practice decisively legislates against it. He notes first that essentialism about biological kinds involves three central tenets: that all and only members of a certain kind possess a common essence, that such real essences give rise to the nominal essences of a kind, and that essences facilitate our inferential practices by causing the co-occurrence of the various superficial properties associated with the kind. The first tenet seems to commit the essentialist to the existence of property types. Thus one could resist it by adopting nominalism about properties. This way of arguing, as Nanay remarks, needn’t carry much weight -- especially if it is motivated by controversial metaphysical rather than biological commitments. Instead, he argues that we should see Ernst Mayr’s influential (now nearly ubiquitous) idea of the biological realm as best described by “population thinking” as pushing us toward nominalism about property types. This move puts Nanay in position to block the second and third tenets as well: property-types play no causal role in evolution; they are statistical abstractions. As such, they cannot explain or facilitate anything -- contra the second and third tenets.

Winning the award for “Best Essay Title in an Edited Volume”, Neil Williams’ essay “Arthritis and Nature’s Joints” attempts to throw another log on essentialism’s funeral pyre. Many diseases, he argues, seem poorly accommodated by essentialism. Rheumatoid arthritis, for example, is presently defined in an exclusively clinical way (as possession of four of seven diagnostic features). Now while it might turn out that these symptoms possess a common cause, it seems a bit implausible to claim that if they are not, that we should be forced to relinquish our practice of construing arthritis as a single disease kind. Williams draws upon the resources of Boyd’s Homeostatic Property Cluster account of kinds in order to make sense of disease kinds. In many ways, diseases seem an ideal test-case for the HPC account. Williams essay thus contributes both to our understanding of disease classification and an apparently flexible approach to natural kinds.

Species taxa play a key role in predicting how populations evolve. The methods employed to carry out such predictions, however, are not free from theory-loaded assumptions. In his essay, “Predicting Populations by Modeling Individuals”, Bruce Glymour addresses the so-called “dynamic” and “statistical” interpretations of evolutionary theory, showing that they mistakenly take their outcomes to be modeling populations, while they are in fact modeling individuals. Glymour argues that the central concept at stake in predicting populations is selection. This is
measured by monitoring either selection differentials or selection gradients, where the former is understood as the difference in fitness among classes of individuals. When considering this method, the way fitness is defined assumes a central role; the model of selection is, in this case, a population genetic model. The latter is a more complex notion, tracing the probability that a certain trait has of causing modifications in phenotypic or genotypic traits -- selection gradients are defined at the individual level and they do not depend on fitness. When adopting this method, the model of selection will be tailored to specific populations, monitoring the causes of survival and reproductive success for its individuals. Glymour argues that the method of following selection gradients has epistemic advantages over methods based on selection differentials, as the former can more easily account for differences at the higher (populations) level in terms of differences at a lower (individual) level.

Another paper in the volume regarding the species problem -- Jason Rheins’ “Similarity and Species Concepts” -- focuses on the role the similarity relation plays in sorting out species. Rheins’ argument starts with a characterization of the similarity relation. Since it is always relative to a respect or parameter, similarity is a more ductile theoretical tool than sameness. Rheins then introduces the metaphysical distinction between immoderate and moderate realism. The first envisages that any universal trait is existentially independent of the existence of any individual. On this view, universals may be said to exist as unrepeatable entities, which are numerically one and the same. The other form of realism, by contrast, sees universals as existing immanently in individuals. A universal cannot exist independently of the existence of some individual which instantiates it. And when the same universal is found in more than one individual it is because we have a repetition of instances. After introducing realist versions for three of species concepts -- biological, ecological, and evolutionary -- Rheins argues that the similarity relation is more suitable than simple qualitative sameness in accommodating such views. Indeed, according to Rheins, the fact that species are divided by a similarity relation does not entail that they are not real. Species concepts based on similarity are consistent with moderate realism based on an objective type of qualitative similarity, whose specifics vary from case to case and provide us with a satisfactory explanatory and predictive power.

The effects of the way organisms are classified into species are felt not only in biological neighborhoods, but -- most remarkably -- in ethical quarters as well. In their essay, “Species Concepts and Natural Goodness”, Crane and Sandler discuss Philippa Foot’s account of natural goodness, according to which an organism’s worth is based on the potential it has for flourishing in ways that are proper for the members of its species. Endorsing a pluralist conception of species, Crane and Sandler explore how well Foot’s account sits with our biological findings and their most direct philosophical consequences. After introducing the various species
concepts that have been advanced by biologists and philosophers of science, the authors argue that Foot’s account rests on what they label “The Axiological Species Concept” (ASC). Central to this is the idea of “life form” -- clearly reminiscent of Aristotelian doctrines and often regarded as synonymous of “species” -- which expresses those traits that are distinctive of the way in which members of a given species live. Although ASC is ultimately deemed as a viable species concept, Crane and Sandler argue that its endorsement needs to be backed up by normative commitments that are foreign to biology, such as those coming from ethology, from the thesis that vice and virtue involve emotions and desires (beyond physiological phenomena), or from the conviction that ethical norms may apply across (very) different environments and cultures. Thus, the natural goodness approach cannot be justified only on the basis of biological findings, rather it calls for some meta-ethical and normative commitments that are independent of them.

The volume concludes with an essay by Kadri Vihvelin, “How to Think About the Free Will/Determinism Debate”, which considers a lurking issue in the natural kinds business. Suppose that we sharpen our conceptual cutlery so much that we attain an accurate knowledge of all the joints of reality and, hence, of the laws governing them. Regardless of whether such laws are probabilistic or not, we might then be in a position to predict, for any instant of the world, what the next future instant can be like, in a way which is independent of the agents’ deliberations. This is a way of capturing the idea that nature might unfold deterministically. On the other hand, the way in which we represent (most of) our actions assumes that, for any of those actions, there is a metaphysical possibility of choosing whether to do it or not - - in these cases we represent ourselves as free agents. But, if determinism is true, this representation is impossible. A certain variety of natural kinds realism thus seems to clash with the idea that we are free agents. According to Vihvelin, the problem of free will versus determinism is indeed the problem of explaining whether this apparent conflict is genuine. In her paper, she first discards a number of misguided ways in which free will and determinism have been conceived. According to her, indeed, the problem of free will versus determinism stems from two obvious facts: first, that determinism prima facie denies that natural kinds realism and freedom of the will are compatible; and secondly, that indeterminism prima facie leaves room for the two being compatible. Vihvelin’s proposal reconciles the two facts. In her view, determinism is compatible with free will, as freedom does not rest on an agent’s actually doing something, but on her ability to so act. In other words, we are free any time we are counterfactually able to do otherwise, even if we do not exercise such an ability.
Notes
Some of this material is adapted from Slater’s (2005) “Monism on the One Hand, Pluralism on the Other”. The authors would like to thank Michael O’Rourke and three anonymous referees for comments that improved this paper.

1. Hacking calls this question “gentle” to differentiate it from a sterner one: “can natural kinds be characterized by essential properties? The gentle question is about what there is, the stern one, about what must be” (1990, 135).
3. Hempel was quick to point out that it merely seemed wrong: for the statement that all ravens are black is, in a sense, a statement not just about ravens, but about the entire universe.
4. He rejected the thought that natural kinds would serve any permanent role in scientific investigation for precisely this reason, being somewhat cautious of a theory-neutral notion of overall similarity -- but that’s another story.
5. It should be noted that “essence” acquires a very different meaning in other philosophical contexts, most notably: in Hegel’s philosophy, where it stands for the deeper structure of reality, in contraposition with the superficial “phenomena”; in Husserl’s phenomenology, in which essences are the content of eidetic intuitions; and in the Existentialist tradition, where it is bestowed a negative connotation in opposition to “existence”. We shall, however, leave these uses of the term on a side as they are not relevant to the philosophical context here under consideration.
6. Even an identical twin or a doppelgänger would not be him.
7. It includes among its champions well-known philosophers such as David Wiggins, Michael Dummett, John Wallace, and Robert Ackermann.
8. Because they are unnecessary for present purposes, here we will ignore some of the distinctions between kinds of sortals, such as the distinction between “phase” and “proper” sortals. The first is predicated of a phase of an entity. For example, “child” is predicated of a phase of a human being’s life, namely childhood. The latter is predicated of the entire life of an entity; for example, “person” is predicated of the entire life of a person.
9. Thus, Wiggins (1979; 1986) seems to defend (i), Brody (1980) defends (ii), and John Wallace (1965), Robert Ackermann (1979), and Jonathan Lowe (1998) defend (iii) -- a view which Wallace attributes to Frege.
10. Natural laws are not *logically* necessary: there is no contradiction or incoherence in imagining that, say, the Law of University Gravitation is false. And yet, it seems clear that laws are somehow “more necessary” than mundane, accidental facts (e.g., that all the coins in my pocket are made of copper). See Lange (2009) for an accessible and insightful discussion into this issue.

12. Kitcher too provides an illustration of the pull of genetic essences. “Structural explanation” often involves investigation into the genetic basis of morphological features -- for example, viral protein sheaths. “We learn that the features that originally interested us depend upon certain properties of the viral genome. At this point our inquiries are transformed. We now regard viruses as grouped not by the superficial patterns that first caught our attention, but by similarities in those properties of the genome to which we appeal in giving our explanations…. The achievement of an explanatory framework goes hand in hand with a scheme for delineating the “real kinds” in nature” (1984, 321-2). Kitcher admits, of course, that this example “mixes science with science fiction” -- as we shall see, the general strategy faces other serious problems.
